CASE REPORT

A 55 yr old male patient presented to the department with left sided pneumothorax and ICD in situ. Patient had shortness of breath and chest pain since two months, he was immediately admitted in a peripheral hospital where ICD (Intercostal drainage tube) was inserted and further chest X-rays showed complete resolution. ICD tube was removed after 3 days and patient was discharged. Three days later patient developed acute shortness of breath, chest X-ray showed hydro-pneumothorax and an ICD was re-inserted. When the chest X-ray showed complete lung expansion, Betadine pleurodesis was performed and subsequently ICD tube was removed. He is a chronic smoker with a Smoking Index (SI)>500 and had Pulmonary Tuberculosis 8 years back for which he had taken complete treatment. After 1 week post ICD removal he again developed shortness of breath and chest x ray (Fig-1) showed Pneumothorax and ICD no. 24 was inserted which relieved him of his breathing difficulties. Patient was discharged with ICD in situ with persistent continuous air leak and referred to our department

Initially on arrival ICD tube was removed and an ICD of increased diameter 32No. (Fig-2) was inserted but it did not help much in improving the patient condition. Further a contrast enhanced CT scan of thorax was performed which suggested the presence of multiple infected bullae and the rupture of an infected bullae communicating with the pleural cavity behind the etiology of recurrent pneumothorax and persistant bronchopleural fistula. He was having history of chronic low grade fever with night sweats but was sputum negative and empirical category 2 anti tuberculous treatment was started, following one week of ATT intake and in view of persisting continuous air leak, patient was posted for flexible bronchoscope guided closure of bullae and bronchopleural fistula with 0.3 % silver nitrate. Procedure was uneventful and immediately post procedure there was drastic improvement and gradually over the following days there was complete absence of air leak suggesting closure of broncho-pleural fistula and ICD tube was removed as chest X-ray shows complete resolution and complete lung expansion (Fig-3).

Patient was discharged on Category 2 ATT and further follow up Chest X rays showed marked resolution of parenchymal infiltrates (Fig-4).

DISCUSSION

A pneumothorax is air in the pleural space, that is, air between the lung and the chest wall. Pneumothoraces can be divided into spontaneous Pneumothoraces, which occur without antecedent trauma or other obvious cause, and traumatic Pneumothoraces, which occur from direct or indirect trauma to the chest. Most secondary spontaneous Pneumothoraces are due to COPD (Chronic Obstructive Pulmonary Disease), although almost every lung disease has been reported to be associated with secondary spontaneous pneumothorax. Tuberculosis was the second leading cause of secondary spontaneous pneumothorax after COPD in endemic areas. COPD patients are sometimes complicated by the presence of emphysematous bullae. A bulla is an air-containing space within the lung parenchyma that arises from destruction, dilatation, and confluence of airspaces distal to terminal bronchioles and is larger than 1 cm in diameter. A superinfection within a bulla can occur with clinical manifestations including fever, cough, purulent sputum production, dyspnea, and pleuritic chest pain. Spontaneous pneumothorax may be a complication of bullous disease, particularly in patients who continue to smoke. The typical presentation is a sudden onset or worsening of dyspnea with or without pleuritic chest pain. Ultrastructural assessments suggest the possibility of air leaking through the wall of the bullae with sloughing of mesothelial cells. Patients with pneumothorax secondary to tuberculosis should have surgery if the airleak persists more than a few days or if they have a relapse. Here in this case patient is been treated with .3% silver nitrate after localization of bronchopulmonary segment with the aid of bronchoscope and methylene blue and the results were highly satisfactory and empirical ATT was started which showed significant clinical and radiological improvement.

CONCLUSION

Pneumothorax is a very common condition and very frequently it is complicated by the presence of broncho-pleural fistula which in turn leads to persistence of ICD tube for a long time there by affecting the quality of life of the patients and additional chance of secondary infection, since a long time surgery is considered as the only option but in patients who are not fit for surgery, Silver nitrate aided Broncho Pleural Fistula closure is an option and is cheaper and less invasive.
