Is Histopathologic Evaluation of the Dental Follicle a Need of Time??

Rozina Vishnani, Pankaj B. Patil, Nilesh Patil, Mouneshkumar C.D., Abhijit Sande

ABSTRACT

Introduction: Previous studies have reported that dental follicle associated with third molar may undergo cystic degeneration or neoplastic transformation leading to formation of odontogenic cysts and tumors. The presence of pericoronal pathosis is generally accepted reason for their extraction. “Radiographic pathology” is define as a Pericoronal radiolucency measuring about 2.5 mm or larger in any dimension. The aim of the study was to evaluate Histopathological changes in Dental Follicle associated with Impacted Mandibular Third Molar.

Material and Methods: This study was conducted in Department of Oral and Maxillofacial Surgery between February 2014 and May 2014, total 50 patients were included in this study aged between 17 to 50 yrs age, out of which 29 males and 21 females who were undergone surgical removal of impacted mandibular third molar showing pericoronal radiolucency less than 2.4 mm. The dental follicle were detached from teeth carefully and sent for histopathological evaluation to the Department of Oral Pathology. The types of pathological changes were recorded based on histopathological report.

Results: Out of 50 patients studied, the results obtained from histopathological reports showed that incidence of chronic nonspecific inflammation (58%), incidence of normal dental follicle (28%) while incidence of cystic changes showed (14%).

Conclusion: Considering the significant incidence of pathological changes in dental follicular tissue, histopathological evaluation of dental follicle is routinely required to prevent any pathological changes in future.

INTRODUCTION

Dental follicle originates from odontogenic ectomesenchyme, is part of the tooth germ and is physiologically involved in the formation of cementum, the periodontal ligament, and alveolar bone. Once the tooth has fully developed inside the jaw, the coronal part of the follicle is termed dental/ pericoronal sac or follicle and occasionally persists adjacent to the crown of unerupted or impacted teeth. It is composed of fibrous connective tissue and frequently contains epithelial residues of odontogenesis, which could be the starting point of pathology. Radiographically, it appears as a thin pericoronal radiolucency considered normal by some authors when it is less than 3mm thick and by others when it is no thicker than 2.5mm. Apart from its important role in eruption physiology, previous studies have reported that the dental follicle may undergo cystic degeneration and/or neoplastic transformation. Recent studies have reported pathological changes in dental follicle of up to 2.5mm. Mandibular third molar are most commonly impacted teeth in oral cavity. Removal of impacted mandibular third molar is common procedure performed in oral surgery. Indications for removal of third molar have generated much discussion in dentistry. Some clinicians advocate prophylactic removal before pathologic changes develop while others propose observation and periodic monitoring. Third molar impaction is a major problem in dentistry. Figures ranging from 9.5% to 39% have been quoted in different populations worldwide. In the Asian Indian population the most common position of impacted third molar is vertical (42%) followed by mesioangular (31%), distoangular (27%) and rarely horizontal. The development of impacted third molars normally spans several years and, problems often develop gradually. Nevertheless, these gradual changes can cause sudden and severe pain, discomfort, pericoronitis, headache and swelling. Some type of pathologic changes like dentigerous cyst, internal resorption, caries, periodontal ligament damage, bone loss distal to second molar and pressure resorption of second molar can be expected eventually in approximately 12% of impacted third molar population and 1.82% of the general population over sustained period of time. The pathologic changes are common in mandibular third molar (8%) compared to maxillary third molars (5.2%). While not every impacted third molar actually causes clinically significant problem, each has a potential.

This research includes histopathological evaluation of the dental follicle after mandibular third molar surgery; we have included 50 patients with unilateral impacted or partially erupted mandibular third molar in age group 17 to 50 years showing pericoronal radiolucency less than 2.4mm. After surgical removal of mandibular third molar, dental follicle was carefully detached from teeth and kept in 10% formalin solution and sent to Department of Oral pathology and microbiology for histopathological evaluation.

Numerous justification for and against prophylactic extraction of asymptomatic impacted third molar had been offered in the past leading to confusion in the mind of practitioners. Numerous studies with conflicting results were conducted on potential of follicular tissues to undergo

pathological alteration.16 Hence, this study aimed to evaluate the histopathologic changes in dental follicle associated with impacted mandibular third molars.

MATERIAL AND METHODS

50 patients who met the inclusion and exclusion criteria were randomly selected from the OPD in Department of Oral and Maxillofacial Surgery between February 2014 and May 2014. The Ethical clearance was obtained from ethical committee in January 2015. Out of the total 50 patients included (based on inclusion and exclusion criteria), 29 were males and 21 were females who underwent surgical removal of impacted mandibular. A written informed consent was taken from the patient before performing Surgical procedure.

Inclusion criteria

Healthy patient in age group 17 to 50 years. Pericoronal radiolucency should be less than 2.4 mm.

Exclusion criteria

Medically compromised patient.

Pericoronal radiolucency > 2.4 mm.

The dental follicles were detached from teeth carefully and were kept in 10% formalin solution and sent for histopathological evaluation to the Department of Oral Pathology. The types of pathological changes were recorded based on histopathological report.

RESULT

A total of 50 dental follicles were histopathologically evaluated. The age of these patients ranged from 17 to 50 years, 29 of them being male patients and 21 female. The results obtained from histopathological reports showed that incidence of chronic nonspecific inflammation (58%), incidence of normal dental follicle (28%) while incidence of cystic changes showed (14%).

On comparison of age group affected by impacted teeth between male and female t = 4.771 and p=0.0001( extremely significant). Thus female with younger age have greater incidence of impacted mandibular third molar (Table-1). Out of 50 cases 32 cases were of impacted 38 out of which 16 were male and 16 were female and 18 cases of impacted 48 out of which 13 were male and 5 were female patients. p = 0.2188 (not significant) chi square value = 1.512 Thus both sides are equally affected.

To determine the mean follicular size ranging from 1 to 2.4 mm following test were done to find any significant radiographic follicular size. For 38 male to female comparison t= 0.5842, p = 0.5634 (not significant). For 48 male to female comparison t = 0.5842, p = 0.0932 (not significant) Male comparison t = 0.6496, p = 0.5215 (not significant). Female comparison t = 2.029 p = 0.0568 (not significant). For all male to female comparison t = 1.06 p = 0.2942 (not significant). Overall comparison between 38 and 48 t = 1.410 p = 0.1650 (not significant). Thus there was no significantly comparable radiographic follicular size (Table-2).

The results obtained from histo-pathological reports showed that incidence of chronic nonspecific inflammation in 29 cases (58%), incidence of normal dental follicle in 14 cases (28%) while incidence of cystic changes in 7 cases (14%). p = 0.4137 (not significant) chi square = 1.765. thus there was no significant cystic changes (Table-3) (Figure-1)

DISCUSSION

The presence of pericoronal pathosis is generally the common reason for the removal of third molars. Pericoronal space surrounding the impacted third molar may represent either a normal or an enlarged dental follicle but alternatively may represent a pathologic entity most commonly a dentigerous cyst.17 Several studies have suggested that the follicular tissue associated with these teeth may have the potential for transforming into cystic and/or neoplastic lesions. Various pathological changes like odontogenic keratocyst, dentigerous cyst, calcifying epithelial odontogenic cyst, odontogenic myxoma etc have been reported.16 However many of these changes are not detectable during clinical or
radiographic examination while they may be found through microscopic analysis. Hence, histopathological evaluation of dental follicle is mostly recommended to evaluate the various cystic changes associated with impacted third molars. In this study histopathological evaluation was carried out of 50 dental follicles from impacted mandibular third molar, which were having radiographic radiolucency less than 2.4mm.

In the present study we analyzed the pathologic changes in both asymptomatic as well as symptomatic cases (showing pericoronitis/chronic irritation).

21 follicles showed odontogenic tissue out of which 14 follicles showed presence of reduced enamel epithelium and underlying connective tissue displayed Odontogenic islands and few areas of ossification, without evidence of cystic lining. These follicles were histopathologically diagnosed as normal dental follicle. While 4 follicles showed presence of 2-3 cell layers of flattened cells, with connective tissue showing odontogenic islands in fibro cellular stroma, diagnosed as dentigerous cyst. The remaining 3 specimens showed presence of epithelial lining of stratified squamous type arranged in arcing pattern, underlying connective tissue showed presence of chronic inflammatory cell infiltration in fibro cellular stroma, diagnosed as radicular cyst.

In this study we found 7 cases of cystic changes out of which 4 cases were reported as dentigerous cyst while 3 cases seen as radicular cyst. Out of 50 cases studied, 29 cases showed chronic nonspecific inflammation suggestive of presence of inflammation in pericoronal region. 14 cases were showing normal routine dental follicle.

Previous similar studies conducted showed variable values ranging from the high rate of cystic changes in Rakprasitkul et al (2001) (58.65% (dentigerous cyst, 50.96%; chronic nonspecific inflammatory tissue, 4.81%; odontogenic keratocyst, 1.92%; ameloblastoma, 0.96%)), to low as in Monica Yadav et al (2001) study (4.44%). Comparing the present study with past studies conducted we have intermediate results (14%).

After extraction of impacted tooth, the follicles are normally discarded and not sent for histopathological examination. In view of results in our study we recommend all tissue extracted should be sent for its histopathological evaluation.

CONCLUSION

Considering the significant incidence of pathological changes in dental follicular tissue, histopathological evaluation of dental follicle is routinely required to prevent any pathological changes in future. We propose more such studies with greater sample size and coupled with immunohistochemical investigations of the same are the need of the hour.
