A Prospective Comparative Study of Needle Aspiration vs Incision and Drainage of Lactational Breast Abscess

Ranjeesh V¹, Swathi Kotha²

ABSTRACT

Introduction: Puerperal breast abscess is a common problem in lactating mothers causing significant morbidity with the incidence ranging from 0.4 to 11% in Indian subcontinent. Study aimed to compare the outcomes of needle aspiration vs incisional drainage of lactational breast abscess with reference to recurrent abscess, time required for complete healing, pain and scar, to study the most common organism in the breast abscess and to study the sensitivity of the organisms seen in breast abscess.

Material and methods: This is a prospective study done from 1st April 2017 to 1st March 2018. All patients who come to outpatient department of RVM Medical College with the diagnosis of lactational breast abscess were taken as study population. Data of 60 patients with clinical features suggestive of puerperal breast abscess was recorded. The patients were then divided into two treatment groups A and B with 30 patients in each group. Patients in group A underwent percutaneous needle aspiration and in group B underwent open surgical drainage.

Results: A total of 60 breast abscesses were treated by these methods. In group A 25 patients were treated successfully with needle aspiration and antibiotics. The mean time for healing is 11 days in 2 cm abscess and longest 23.5 days in 5 cm abscess. 7 abscesses showed growth of S.aureus, 17 showed MRSA, 4 showed no growth, 2 abscesses showed other rarer organisms. Success rate of aspiration is 83%. This is an outpatient procedure and is cost effective. Patient satisfaction is more in aspiration group. Group B patients underwent incision and drainage but it is associated with cessation of breast feeding, cumbersome scar, and prolonged healing times. Mean time of healing in 3 cm abscess is 25.5 days and 5 cm abscess is 30 days.

Conclusion: We conclude that needle aspiration in the management of uniloculated puerperal breast abscess is an effective method of treatment.

Keywords: Puerperium, Lactational Breast Abscess, Needle Aspiration, Incision Drainage

INTRODUCTION

Puerperal or lactational breast abscess is a common problem in lactating mothers causing significant morbidity. The incidence of breast abscesses in lactational mastitis ranges from 0.4 to 11% in Indian subcontinent¹. Risk factors for lactational breast abscess are primipara, gestational age >40 weeks and history of mastitis. A stage of mastitis precedes abscess formation. Sonography became an important diagnostic modality in the diagnosis of breast abscess which differentiates between mastitis and abscess². Non puerperal breast abscess occurs outside the breast feeding period. They are seen in obese, tobacco smokers³. Other types of breast abscesses include tubercular breast abscess, granulomatous mastitis, fungal mastitis. The traditional management of breast abscess was incision and drainage, but significant morbidity was associated with the procedure. Moreover this is an inpatient procedure and patients are exposed to the risks of general anaesthesia. The treatment of the breast abscesses shifted from a conventional approach incision and drainage to a more conservative approach needle aspiration in the recent years⁴.

It is recently reported that multiple needle aspirations with antibiotic coverage as an outpatient procedure is an effective alternative in the treatment of smaller breast abscesses. The aspiration of the breast abscess was undertaken with or without the use of ultrasound. The studies also concluded that needle aspiration is a cost effective method⁵-⁸. Our hospital registers approximately 100 -120 patients with a diagnosis of breast abscess every year, out of which 60-70 are lactational breast abscesses. The purpose of our study is to find out the efficacy of needle aspiration in the management of lactational breast abscess.

Study aimed to compare the outcomes of needle aspiration vs incisional drainage of lactational breast abscess with reference to
- Recurrent abscess
- Time required for complete healing
- Pain
- Scar

And to study the most common organism in the breast abscesses and study the sensitivity of the organisms seen in breast abscess.

MATERIAL AND METHODS

This is a prospective study done from 1st April 2017 to 1st March 2018. All patients who come to outpatient department of RVM Medical College with the primary diagnosis of

lactational breast abscess were taken as study population. Data of 60 patients with clinical features suggestive of puerperal breast abscess (fever, pain, swelling, redness of breast associated with localized tenderness) and who gave consent was recorded. The diagnosis was confirmed by ultrasound evidence of liquefaction with long axis diameter for consideration of size. The patients were then divided into two treatment groups A and B with 30 patients in each group. Patients with co-morbid conditions were excluded from the study.

Patients with group A, underwent percutaneous needle aspiration as an outpatient basis using 18 gauze needle attached with 20 cc syringe. All the patients were encouraged for breast feeding. Further aspirations if needed were done at an interval of 5-7 days till the resolution of signs and symptoms. There are two end points in the management, when no further pus is aspirated and confirmation of absence of residual abscess by ultrasound done after 2-3 days after 1st endpoint. Failure of treatment in group was declared on the basis of persistence of symptoms and signs after 5 aspirations. Amoxicillin + Clavulanic acid was given to all the patients till culture sensitivity report. Antibiotic is stepped up if the culture shows resistance to amoxicillin clavulanate. A total of 7 days of antibiotics were given to all patients. Patients are encouraged for breast feeding from both the sides.

Patients with group B underwent open surgical drainage under general anaesthesia as an inpatient basis. Injection Amoxicillin + clavulanic acid was given to the patient on the day of surgery and shifted to oral medication on discharge. All the patients stayed for 1 day in the hospital. Daily dressing with packing gauze was done till the resolution of sign and symptoms and complete healing of wound as end point of management. Antibiotic was given for 7 days to all the patients. All patients were encouraged for breast feeding from opposite side with expression of milk on the same side. Pain is a subjective phenomenon. There are no biochemical parameters for measurement of pain. Pain is measured by Visual pain analog scale. But we selected a different method of measuring the pain. The number of analgesics required by the patient during the course of the treatment was taken into account.

**Inclusion criteria**
1) Abscesses of size < 5cm
2) All lactational breast abscess

**Exclusion criteria**
1) Tubercular abscess
2) Chronic Granulomatous mastitis
3) Galactocele
4) Fungal infection
5) Non Lactational breast abscess

**Sample size: 60**
- Group A: 30
- Group B: 30

Using G power software the sample size of 60 was obtained which is sufficient to obtain 80% power of study.

### DATA ANALYSIS

Statistical analysis of the data was carried out with the help of SPSS (version 20) for Windows package (SPSS Science, Chicago, IL, USA). Student’s t-test was used to test statistical significance of difference in means of duration of hospital stay or in mean time required for complete healing between two independent groups. Z test for proportions (or Fisher’s exact test in case of small frequencies in cell) was used to examine the significance of proportion of patients with postoperative pain or residual abscess between the two groups. p value < 0.05 was considered significant.

### RESULTS

In our study maximum number of patients were in greater than 25 years. But we selected a different method of measuring the pain. The number of analgesics required by the patient during the course of the treatment was taken into account.

than 30 years and the smallest abscess was of size 2 cm and the largest was 5cm (table-2).

In our study there were 28 right sided and 32 left sided abscesses (table-3).

Our study reported a total of 36 abscesses in the lower quadrant. Even if the abscess was located in more than one quadrant, we had considered that quadrant of the abscess which had the maximum diameter (table-4).

In the study 53.3% of the patients were primipara and 46.7% were multipara (table-5).

Maximum number of patients (38) had Lower Segment Caesarean Section (table-6). In our study more number of patients were presented within the first 6 weeks (85%) (table-7).

In our study we had noticed 63.3% of the abscesses grew Methicillin resistant Staphylococcus aureus (MRSA). This is followed by Staphylococcus aureus (25%). Other organisms identified in the culture are Corynebacterium diphtheria, S.agalactea, and S.epidermidis (table-8).

The mean duration of healing in group A and group B was 19.200 days and 30.1667 days respectively. Single aspiration was required in 1 patient and 5 aspirations were required in 13 patients, 3 aspirations were required in 3 patients, 4 aspirations were required in 1 patient and 5 aspirations were required in 1 patient (table-9).

Out of 30 patients in group A only 25 were successfully treated by aspiration. In group B all the 30 patients were treated by incision and drainage. The failure rate of aspiration was 17% (table-10).

Pain
During the course of treatment all the patients in both the groups received combiflam (Paracetamol + Ibuprofen) as analgesic agent. Abscess was a painful condition and all the patients of Group A were relieved of pain after aspiration but pain persisted with subsequent collection of pus during the next follow up. All the patients had taken combiflam during the day of aspiration thrice daily and thereafter whenever necessary. In Group B, patients were relieved of pain immediately after incision and drainage. But the pain was intolerable during the dressings and all the patients had taken the NSAID for a minimum of 5 days thrice daily.

Scar
In our study, group A patients all the patients who were successfully treated by aspiration (25) had no scar, those who underwent incision and drainage (5) had scar. In group B all the patients had scar.

Sensitivity of drugs
In our study all the patients received 7 days of antibiotic course. All the patients in both group A and group B were started on Amoxicillin and Clavulanic acid till the culture sensitivity report. In the patients whose abscess had shown the growth of S.aureus, Amoxicillin + Clavulanic acid was prescribed and in patients whose abscess showed the growth of MRSA, Linezolid was given for 7 days. Staphylococcus aureus, S.agalactea, S.epidermidis showed sensitivity to Amoxicillin and Clavulanic acid. Corynebacterium showed sensitivity to macrolide group of drugs. Amoxicillin + Clavulanic acid was given for 7 days followed by Erythromycin for 7 more days.

DISCUSSION

Age
In our study the youngest patient was 23 years and the oldest was 38 years old. The mean age of all the patients in the study was 30 years. The mean age was different in different studies6-10. Ulitzsch et al11 from Sweden and AF Christensen et al12 from Denmark had reported 32 years of mean age in their study. This implies the age of pregnancy in the European countries is above 25 years. In Gojen Singh et al he considered non lactating patients which was the reason for the mean age of 32 years in his study10.

Size of abscess
In our study the smallest abscess was of size 2 cm and the largest was 5 cm. Based on success rate with respect to size of abscess in multiple studies around the world we had decided the cut off point for maximum size to be 5 cm10-13.

Site of abscess
Our study reported a total of 36 abscesses in the lower quadrant. Studies of Singh et al10 and Chandika et al14 reported most of the breast abscesses in the upper outer quadrant. The reason for the observation in our study might be because the milk from the lower quadrant of the breast would have to move against the gravity and has more chance of stasis of the milk in the ducts of lower quadrant. Mastitis...
and abscesses occurs when there is milk stasis. Secondly the sample size is too small to reach a conclusion, so it might be just an observation in our study which requires further evaluation.

**Parity and mode of delivery**
In our study 53.3% of the patients were primipara (Table 5). This observation of our study very well corroborates with the data of different studies. Kamal Kataria et al from said that the risk factors for the formation of breast abscess were first pregnancy, mastitis, pregnancy more than 41 weeks. The reason was in primipara because of the lack of experience regarding the positioning of the baby, nipple areola care and poor hygiene predisposes for the formation of breast abscesses. This was collaborated from the data around the world.

63.3% of the patients in my study underwent caesarean section as against 37% of normal vaginal delivery (Table 6). High percentage of breast abscesses in their group can be explained by the fact that operative procedure with anaesthesia, post operative analgesia and drowsiness, difficulty in sitting up to breast feed, delay in initiation of breastfeeding. No study had reported any relation between the mode of delivery with the development of breast abscesses.

**onset of symptoms from intiation of breast feeding**
In our study more number of patients were presented within the first 6 weeks (85%). Kamal Kataria et al said that most of the lactational abscesses occurs during 2 periods within first 4 weeks of breast feeding due to inexperience and secondly after 6 months due to trauma to the nipple by the teeth of the infant. Dieter Ulitzsch et al reported a mean time of 5.4 weeks for the development of abscess after delivery.

**Organisms identified**
In our study we noticed 63.3% of the abscesses grow Methicillin resistant Staphylococcus aureus (MRSA). This is followed by Staphylococcus aureus (25%). All the previous studies reported that Staphylococcus aureus was the most common organism found in the cultures of breast abscess. Many other studies also confirmed that the most common organism obtained in culture was S. aureus.

**Residual abscess**
Kaushal S et al in their study found 3 patients with recurrence of the abscess. Chandika et al in their study noticed no recurrence in the patients treated with aspiration but he noticed recurrences in incision and drainage group.

Sarhan HH in their study said the importance of ultrasound in the follow up to see for residual abscess in the absence of clinically evident abscess. Elagili et al concluded multiloculated abscess associated with approximately 50% failure to cure by aspiration. Hook et al in his study concluded that abscess of size > 3cm is difficult to treat by aspiration. Kaushal S et al and many others noticed a failure rate of 17%. Smaller size of the abscess can be treated by aspiration and larger sized abscesses needed incision and drainage.

**Scar**
Imperiale et al in their study said the cosmetic result was optimal in all cases. Kaushal S et al said that all the patients who underwent incision and drainage complained of an ugly scar. Dieter Ulitzsch et al and Singh et al in their study reported 96% of patients treated by aspiration were satisfied by the cosmetic results.

According to Chandika et al aspiration needle was a highly accepted modality. The high acceptance rate may be because of the convenience of the procedure which was an outpatient procedure and had no wound to nurse on and absence of scar.

**Success rate**
The success rate of needle aspiration in our study is 83%. This correlated with the success rate of certain studies. JM Dixon and Tewari noticed a 100% success rate in their study. Many studies reported a success rate of 80 – 90%.

**CONCLUSION**
We conclude that percutaneous needle aspiration is an effective method of treatment for uniloculated small breast abscesses. Incision and drainage should be considered when aspiration fails or when the size of the abscess is large.
